**ABSTRACT**

Tuberous sclerosis, also known as Bourneville's disease, is a rare autosomal dominant genetic disorder classically characterized by the triad of mental retardation, seizures, and facial angiofibromas. We reported a case of 35 year old female with Tuberous sclerosis complex syndrome presented with facial angiofibromas, pulmonary cyst, pancreas hypoplasia, angiomyolipomas of the bilateral kidney and subependymal nodules.

**Keywords:** Tuberous sclerosis complex, facial angiofibromas, angiomyolipomas of the bilateral kidney, subependymal nodules.

**INTRODUCTION**

The name, composed of the Latin *tuber* (swelling) and the Greek *skleros* (hard), refers to the pathological finding of thick, firm, and pale gyri, called "tubers", in the brains of patients post mortem. These tubers were first described by Desire-Magloire Bourneville in 1880. The cortical manifestations may sometimes still be known by the eponym Bourneville's disease. The full name of "tuberosous sclerosis complex" is preferred among medical professionals and researchers today because the disease has manifestations outside of the brain. [¹]

Tuberous sclerosis complex (TSC) is a rare multisystem genetic disease that causes benign tumors to grow in the brain and on other vital organs such as the kidneys, heart, liver, eyes, lungs, and skin. A combination of symptoms may include seizures, intellectual disability, developmental delay, behavioral problems, skin abnormalities, and lung and kidney disease. TSC occurs in all races and ethnic groups, and in both genders. The live-birth prevalence is estimated to be between 10 and 16 cases per 100,000. TSC is caused by a mutation of either of two genes, *TSC1* and *TSC2*, which code for the proteins hamartin and tuberin, respectively. These proteins act as tumor growth suppressors, agents that regulate cell proliferation and differentiation. [²]

**CASE REPORT**

A 30 years old female presented to emergency department with the history of first episode of generalised tonic clonic convulsion. Patient was born of non-consanguineous marriage. None of the family member was known to have similar complaints.

On examination, patient had multiple hyperpigmented papules over the nasolabial region Adenoma sebaceum (Figure 1), shagreen patch present over left shoulder and back (Figure 2) and perungual fibroma (Figure 3). Systemic examination, slit lamp, fundus examination revealed no
abnormalities. Her Intelligence Quotient testing was done which was normal.

Figure 1: Adenoma sebaceum

Figure 2: Shagreen patch

Figure 3: Periungual fibroma

Figure 4: Echogenic lesions at the upper pole of right kidney

USG abdomen revealed, right kidney measuring (111*47) mm² in size and left kidney measuring (99*55)mm² in size. There is large ill defined exophytic echogenic lesion noted in relation to upper mid of right kidney. Left kidney show altered echo textured and large ill defined echogenic lesion noted in relation to upper mid of left kidney. P/O Benign lesion Angiomyolipoma (Figure 4).

Figure 5: Subependymal nodules

Figure 6: Renal angiomyolipoma
Bilateral mammography - Normal CT scan of brain shows Subependymal nodules involving ependymal surface of both lateral ventricle, Old infarct involving right temporal region, Cerebral oedema, Multiple sclerotic lesion involving skull vault (Figure 5).

CT scan of abdomen shows multiple bilateral renal angiomylolipomas, pancreas hypoplasia (Figure 6).

Finding of MRI brain were- (Figure 7)
1. Multiple recent ischemic areas involving right parieto-temporo-occipital and left parietal paramedian cortical-subcortical region.
2. Multiple small subcentimeter size altered signal lesions in the ependymal region along frontal horn, body and atrium of both the lateral ventricles, represents subependymal nodules
3. Subtle focal non-enhancing altered signal along the bilateral frontal cortical region, may represent cortical tubers/edema.

2D Echo - normal
Patient was treated with antiepileptic drugs and Oncologist advised to start Tab. Everolimus.

DISCUSSION
Tuberous sclerosis complex (TSC) is a rare genetic disorder with heterogeneous presentation varying from severe mental retardation and incapacitating seizures to normal intelligence and an absence of seizure, often within the same family. It is due to inactivating mutation in one of the two genes, TSC1 encoding hamartin, or TSC2 encoding tuberin2.

The major neurological manifestations of tuberous sclerosis complex are seizures, autism, developmental delay and behavioral and psychiatric disorder. Seizure is present in about 80-90% of patient which begins during the first year of life; varies from subtle focal seizure, infantile spasm, to generalized seizure. [3-5]

Manifestations of tuberous sclerosis can become apparent in persons of any age, but most patients have clinical symptoms before they are aged 10 years. The disease develops as an abnormal growth of ectodermic cells producing tumors extending to areas of the head, heart, brain, eyes, skin and kidneys. [6] In 2012, the International Tuberous Sclerosis Complex Consensus Conference published new diagnostic criteria for diagnosis of tuberous sclerosis. (Table 1). [7]

Table: CLINICAL DIAGNOSTIC CRITERIA [7]

Definite diagnosis: Two major features or one major feature with 2 minor features Possible diagnosis: Either one major feature or 2 minor features According
to the criteria the patient reported had more than 2 major criteria and was considered as TSC. There are many cutaneous stigmata of TSC and they are seen in almost all patients with the disorder. The most common and earliest skin finding in TSC is multiple hypopigmented macules (also called ashleaf spots). Adenoma sebaceum is a hamartoma composed of connective and vascular elements and is properly termed an angiofibroma they are pathognomonic of TSC. Angiofibromas form discrete pink papules on the malar region of the face in 70% of TSC patients. Patients with tuberous sclerosis complex (TSC) can develop a number of renal lesions, the most common being angiomylolipomas and cysts. Renal cysts are rarely symptomatic in patients with TSC, unless the patient exhibits the polycystic kidney variety of TSC. It has been reported that up to 80% of adult patients with TSC will develop angiomylipoma and that these lesions tend to increase in size over time.

The intracranial features of TSC are cortical or subcortical tubers, subependymal nodules, subependymal giant cell astrocytomas, and white matter radial migration lines. Tubers are most commonly found in the cerebrum, 90% being present in the frontal lobes. On NECT in early stages tubers appear as low density subcortical masses. In late stages the appear isodense to barin. 50% calcify by the age of 10 years. On T2- weighted and FLAIR MR images, tubers typically appear as areas of increased signal intensity in the cortical and subcortical regions. Tubers exhibit contrast enhancement in approximately 3–4% of cases. Ninety-five percent of tubers are multiple, but in rare instances solitary cortical tubers are seen. Less commonly tubers are present in the cerebellum.

Subependymal nodules (SEN) are found on the walls of the lateral ventricles and are either discrete or roughly confluent areas of rounded hypertrophic tissue. Typically benign, subependymal nodules can degenerate into sub ependymal giant cell astrocytomas in 5–10% of cases. On NECT the nodules occur anywhere along the ventricular surface but are most commonly found at the caudothalamic groove in the region of the foramen of Monro. 50% calcify. Enhancing SEN may be suspicious for subependymal giant cell astrocytoma. Microcephaly may be found in patients with TSC. The cerebral gray and white matter volumes are lower than those of age matched controls. Pulmonary lymphangioleiomyomatosis probably affects 1-3% of patients with tuberous sclerosis.

A cardiac rhabdomyoma can be discovered using echocardiography in approximately 50% of TSC patients. However, the incidence in the newborn may be as high as 90% and in adults as low as 20%. Rhabdomyomas have been diagnosed by two-dimensional echocardiography in the fetus. Ophthalmic features associated with TSC can be divided into retinal and non-retinal. The retinal lesions are known as astrocytic hamartomas. Non retinal lesions include coloboma, angoifibroma of the eyelid and papilledema (related to hydrocephalus).

Multiple bony changes have been described in TSC of which sclerotic lesions are the most common. Hyperostosis of inner table of skull, periosteal new bone formation, scoliosis, and bone cysts have also been described. Patients with Tuberous sclerosis complex (TSC) range from intellectually normal to severely mentally retarded. TSC is often associated with mental retardation (in 70% of cases) and epilepsy (90%). Seizures are the most common neurologic symptom of TSC occurring in 92% of patients. Prognosis of the disease depends on the severity or multiplicity of organ involvement.

**ROLE OF EVEROLIMUS IN TUBEROUS SCLEROSIS**

Since the discovery of rapamycin in the 1960s, mTOR inhibitors, particularly everolimus, have been used to prevent solid organ transplant rejection, augment anticancer treatment regimens, and prevent
neovascularization of artificial cardiac stents. [18] Following the identification of the genes involved in TSC in the 1990s, [19] evidence revealed mutations or deletions that allowed mTOR activity to go unchecked (Figure 8). [20-22] Subsequent clinical trials in patients with TSC led to the approval of the mTOR inhibitor everolimus for TSC-associated subependymal giant cell astrocytoma (SEGA) by US Food and Drug Administration (FDA) in 2010; [23] it became the first-ever approved therapy for patients with TSC. Everolimus was also approved by the FDA in 2012 to treat renal angiomyolipomas in patients with TSC. [23]

**CONCLUSION**

The chance of progression to malignancy is more. Early Diagnosis and treatment with Everolimus is very important. Because this drug have the potential to not only treat other manifestations of TSC, such as angiofibromas, cardiac rhabdomyomas, LAM, and epilepsy, but they may also have a role in modifying disease progression at a very young age.
