ABSTRACT

Introduction: Intercostal (IC) muscles help in upward and outward movement of the ribs which results in increase in antero-posterior diameter of the thoracic cavity. The use of manual stretching procedure is prevalent in respiratory physiotherapy to improve pulmonary functions.

Objective: To determine the effect of Intercostal (IC) stretch and breathing control in improving the lung function parameters (Forced Expiratory Volume) in the first second (FEV1), Forced Vital Capacity (FVC) and FEV1/FVC % and respiratory rate among healthy young females.

Methodology: Thirty healthy female subjects, age 19-24 years were recruited based on inclusion and exclusion criteria and written informed consent was taken. Participant’s assessment and evaluation was done. Lung function parameters and respiratory rate were recorded before undergoing procedure. Subjects underwent three IC stretch for ten breaths on the inspiratory phase of the respiratory cycle followed by breathing control exercises with a time gap of 2-3 minutes in semi recumbent position. Immediately, following intervention, the respiratory rates recorded and lung function test were performed using spirometry to evaluate the effect of intervention. The total sessions last for 15 minutes.

Result: By applying Paired t-test for Pre and Post values of FEV1, FVC, FEV1/FVC and respiratory rate p-value obtained was 0.0001, which was statistically significant. This suggested that IC stretching with breathing control is more effective in improving dynamic lung parameters.

Conclusion: The study concludes that there was a significant improvement in the lung function (FVC, FEV1, FEV1 /FVC) and respiratory rate among the healthy young females who underwent IC stretch followed by breathing control exercise.

Keywords: Intercostal Stretch, Breathing Exercises, Lung Function Parameters.

INTRODUCTION

The respiratory system consists primarily of the lungs, whose main function is to ensure gas exchanges with the environment, and the thoracic wall, which moves as a result of continual muscle action1. The thoracic wall represents the thoraco-abdominal area composed of the rib cage and the abdomen, separated by the diaphragm2,3. Thus, normal thoraco-abdominal motion consists of expansion and retraction of these compartments during inspiration and expiration, respectively4,5.

Breathing pattern and thoraco-abdominal motion may be influenced by several factors, such as the individual’s positioning6,7, age7,8, sex7, respiratory overload9, neuromuscular diseases10, lung diseases associated with increased airway resistance4,11,12 and chronic obstructive pulmonary disease (COPD)5,13-15. Higher rates of asynchrony may be related to worse
Deepshikha Trivedi et.al. Effect of intercostal stretch and breathing control exercise on lung function among healthy young females.

prognosis and significantly greater mortality.\textsuperscript{13}

Although the rib cage and abdomen move in unison, each of the compartments has independence of movement.\textsuperscript{16} When the displacement between the compartments ceases to be harmonious, the thoraco-abdominal motion becomes asynchronous.\textsuperscript{4,5,17} Healthy men and women in different age groups present symmetry between the movements on the right and left sides of the chest and abdomen.\textsuperscript{18}

In relation to sex, a study that made comparisons between men and women showed that there were differences in respiratory times.\textsuperscript{3} The inspiratory time, expiratory time, and total time of the respiratory cycle were shorter among the women. In addition, the women presented higher respiratory frequency, thus suggesting that they tended to breathe more rapidly than the men. In the analysis of thoraco-abdominal motion during quiet breathing, men and women presented the same response.\textsuperscript{3,7}

Intercostal (IC) muscles are diverse and widely spread throughout the rib cage. These muscles help in upward and outward movement of the ribs which results in increase in antero-posterior diameter of the thoracic cavity.\textsuperscript{19} The IC muscles help both in inspiration and forced expiration.

Even though these muscles engage in respiration their activities are fewer during active contraction among normal healthy adults.\textsuperscript{20} Various research studies demonstrated that IC stretching improved expired tidal volume, decreased the level of dyspnea and increased chest expansion clinically which results in better gaseous exchange in human subjects.\textsuperscript{21,22}

IC stretch is performed actively by thoracic mobility exercises. Passively IC stretch can be performed by thoracic rotation, midsternum rotation, lateral thoracic stretching, through thoracic mobility exercises as well as through manual stretching of IC spaces.\textsuperscript{21}

The external IC muscles which are helpful during inspiration showed a higher discharge activity during forcible inhalation. Similarly, a stretch of 15 micrometers applied to IC spaces showed an increase in muscle activity in cats.\textsuperscript{23} The increase in muscle activity of the IC muscles could lead to increase in lung volume and capacities.

According to Puckree,\textsuperscript{24} IC stretching and controlled breathing is effective in improving breathing pattern and respiratory muscle activity among healthy conscious adults. However; none of the research studies examined the effect of IC stretching on dynamic pulmonary function parameters among healthy subjects. Morphologically intercostal muscles displayed a variation in fiber size and atrophy among obstructive lung disease subjects.\textsuperscript{25}

Hence, a change in pulmonary function parameters while performing IC stretching and controlled breathing might benefit to a particular population where respiratory compromise has been demonstrated due to poor IC muscle function. Therefore, the main purpose of the study was to observe the effect of IC stretching and controlled breathing on pulmonary function parameters.

**PROCEDURE**

Patients selected for the project were explained about the study and written consent was taken from them.

**Respiratory rate** Before participation, all subjects underwent resting respiratory rate measurement. Initially the study subjects were requested to lie on a semi recumbent position and readings taken after 3 minutes of resting using auscultation methods. The method adopted in this study to measure respiratory rate was reliable according to a protocol described earlier.\textsuperscript{26}

**Pulmonary function test** The ventilator parameters such as forced expiratory volume in 1st second (FEV1), forced vital capacity (FVC) and forced expiratory volume in first second percentage (FEV1%), were measured by pulmonary function test. A pulmonary function test was carried out by using the handheld spirometer to
Deepshikha Trivedi et al. Effect of intercostal stretch and breathing control exercise on lung function among healthy young females.

estimate the dynamic lung function parameters. Participant’s details were taken before pulmonary function testing such as age; height and weight using SECA weight and height scale (Vogel & Halke, Hamburg, Germany). Then, the variables were keyed into the Pony Fx Cosmed, Italy, spirometer. According to the (ATS)/(ERS) task force, spirometry training and testing were performed to ensure quality. Testing was carried out in sitting position and rest interspersed between each of the three tests. The participants were requested to perform at least three trials and the best of the three values for the manoeuvre such as slow vital capacity and forced vital capacity was taken by the same physiotherapist as suggested by ATS/ERS task force. The spirometry test was preceded with IC stretch.

IC stretch and breathing control Initially a stretch was applied by the same physiotherapist on the left-side midway between the midaxillary line and a line through the nipple in the downward direction of the third IC space. The IC stretch was applied by the physiotherapist manually with the help of index finger over the third IC spaces in a caudad-cephalad direction to the upper borders of the fourth rib. Enough care was paid to avoid compression of the chest wall. Breathing control exercises were performed followed by IC stretching. This was performed in a comfortable semi recumbent position with a pillow under both knees. Participants were encouraged to place their hands over the upper abdomen. As the subject breathed in, the hands were placed over the epigastric region to feel the rise; as they breathed out, the hand sank.

Immediately, following intervention, the respiratory rates recorded and pulmonary function test were performed using spirometry to evaluate the effect of intervention. Subjects underwent three IC stretch and breathing control exercises with a time gap of 2-3 minutes. Each stretch was employed for ten breaths throughout the inspiratory phase of the respiratory cycle.

The total sessions last for 15 minutes.

RESULT

Table 1: Pre and Post Mean ± Standard Deviation (SD) of FEV₁ Values

**Graph 4:**

Inference: The comparison of pre and post test values of respiratory rate showed the lowered respiratory rate in post intervention test ($t = 4.52$, $p = 0.0001$)

**Discussion**

This study was done to find out the effect of Intercostal stretch and breathing control exercise on lung function among healthy young females in the age group of 19-24 years. The subjects were taken from Dr. D.Y. Patil college of Physiotherapy, Pimpri, Pune.

The findings of this study showed the improvement in lung function (FEV1, FVC, FEV1/FVC) and respiratory rate among healthy conscious females who were given IC stretch with breathing control exercises.

The result of this study shows a significant increase in the lung function post IC stretch and breathing control exercise. The overall increase in mean post treatment values were FEV1 = 2.17 ± 0.24, FVC = 2.29 ± 0.26, FEV1/FVC = 95.16 ± 3.02.

The changes in lung function is due to the firing discharged from the muscle spindle during a passive stretch phase. IC stretching activates the stretch receptors in the chest wall, thereby distending thorax which could be neurologically linked to medulla with efferent nerve cells. The afferents, that innervate the margins of diaphragm activates the reflex which alters the pulmonary parameters.

The IC enhances the chest wall elevation and thereby increases the expansion by improving intra-thoracic lung volume which contributes to improve the flow rate percentage. This may contribute in increasing the ventilatory capacity (tidal volume), minute ventilation and oxygen status.

As studied by Threlkel32 by applying manual techniques such as IC stretch produces a suitable amount of plastic deformation of connective tissue which enhances mobility at joints. Therefore, the result of this study suggests that IC stretch was an effective treatment parameter.
There is increase in the value of lung function post IC stretch and breathing exercise which indicates improvement in the lung function. It can be due to the semi-recumbent position during the breathing exercise as in this position there is posterior pelvic tilt and gravity assist the diaphragm in functioning effectively in its role as the primary muscle of inspiration.

There is also significant decrease in the respiratory rate post IC stretch and breathing control exercise (respiratory rate = 18.2 ± 0.32). The rate of respiration is lowered, as the semi-recumbent position during breathing control exercise helps to improve tidal volume and lowers the respiratory rate. As this position gives mechanical advantage by decreasing the pressure of the abdominal organs over the diaphragm and helps the diaphragm to work efficiently thereby increasing the chest expansion and giving more space for the lung volumes. This may be one of the reasons for the significant improvement seen post breathing control exercises along with IC stretch over the taken lung function parameters.

Few studies have proven the improvement in the breathing pattern can be due to localized stretch in the third ICs, showing a deeper breathing pattern, greater activities on parasternal ICs, electromyographic activities which resulted in an increase in tidal volume and a decrease in breathing frequency among healthy subjects.

A possible limitation of the study was quantification of stretch pressure was not performed and it’s uncertain how far these stretch receptors stimulated to evoke response. The sample size of the study was very low with very short duration of the study.

CONCLUSION

The study concludes that there was a significant improvement in the lung function (FVC, FEV\textsubscript{1}, FEV\textsubscript{1}/FVC) and respiratory rate among the healthy young females who underwent IC stretch followed by breathing control exercise.
