ABSTRACT

BACKGROUND: Radial artery is the smaller terminal branch of brachial artery. Abnormal variations in the anatomy of radial artery may produce an iatrogenic injury leading to undesired complications.

MATERIALS & METHODS: Study was carried out on 18 formalin fixed cadavers i.e. 36 limbs of adult age in the Department of Anatomy. Arm and forearm of both upper limbs were carefully dissected to note the variation in the origin of Radial artery.

RESULT: Unilateral Variations of high origin of Radial artery were observed in two cases (5.55%). In first case, radial artery was originated from right brachial artery 13.5 centimetre above the intercondylar line while in second case it was 19 centimetres above the intercondylar line.

CONCLUSION: In recent times, there has been an increase in the use of radial artery for various diagnostic & invasive procedures which requires the qualified apprehension of the variant anatomy to avoid iatrogenic injury and perform safe procedures.

Key Words: Superficial Radial artery, High origin, Invasive procedures

INTRODUCTION

The insight of the course and the relationships of upper limb vasculature accounts for a lot of diagnostic measures and handful surgical approaches. [1] Variations in the vasculature of the upper extremity are due to defects in embryonic development of the vascular plexus of upper limb bud. [2] The present study was performed to find the origin of radial artery and evaluation of the data by correlating with the existing literature along with its embryological explanation and clinical significance.

Classically, the radial artery arises as a smallest terminal branch from brachial artery at the level of the neck of radius, 1 centimeter below the bend of elbow. It traverses deep to the brachioradialis muscle in the forearm and terminates in the hand by forming the deep palmar arch after anastomosing with the deep branch of the ulnar artery. [3] A high origin of the radial artery is the most common vascular pattern variation of the upper extremity which evokes various clinical interests. [4,5] Incidence of high origin of radial artery varies from 4.17% to 15.60% in cadavers and embryos, [6] whereas in angiographic images, the incidence varies from 8.00% to 24.40%. [7]

MATERIALS & METHODS
The current study was done in the Department of Anatomy, Rural Medical College, Loni, and Maharashtra, India on 18 formalin fixed cadavers of both sexes i.e. 36 limbs of adult age as a part of routine dissection program for undergraduates. Arm and forearm of both sides were carefully dissected to note the variation in the origin of radial artery. Photographs were taken using a digital camera. Limbs with the mark of any pervious surgeries or any mode of damage in that area were excluded from the study.

**OBSERVATIONS AND RESULTS**

Unilateral variations in the origin of radial artery with an incidence of 5.55% were observed in the right upper limbs of two cadavers.

**FIRST CASE** (Fig:1) The radial artery originated from the anteromedial surface of the right brachial artery 13.5 centimeter above the intercondylar line just inferior to the insertion of the coracobrachialis muscle. The artery was tortuous and first traversed along the medial border of biceps muscle along with brachioulnar artery and medial nerve then at a distance of 10 centimeters above the intercondylar line it crossed superficially the brachioulnar artery and median nerve.

**SECOND CASE** (Fig:2) The radial artery originated from the anteromedial surface of the right brachial artery 19 centimeter above the intercondylar line after giving the profunda brachii artery. In the arm initially the radial artery traversed medial to the median nerve along with the brachioulnar artery. In the middle third of arm the brachioulnar and radial artery adopted a superficial oblique course covered only by the brachial fascia. In the lower third of the arm at the distance of 8 centimeters above the intercondylar line the radial artery crossed over the median nerve to its lateral side.

**DISCUSSION**
Normally an anatomist focuses on the rare anatomical variations but the arterial variations that occur frequently have a greater clinical significance as they are more likely to be encountered. Most of the times radial artery is used in surgical procedures such as when raising a radial forearm flap, as graft for coronary bypass and intrarsial approach during coronary interventions (Valsecchi et al 2006, Funk et al 1995, Pelin et al 2006). For coronary procedure the trans radial approach is widely accepted then the trans femoral and/or trans brachial techniques because it reduces the site complications. Furthermore, the radial artery is chosen because it is not accompanied by major veins or nerves.

As shown in Table 1 Dubreuil and Chamberdelhas reported 72 cases of high origin of radial artery out of 136 cases in which 19 arose from the axillary artery. McComark et al has studied 750 extremities of cadavers and noted high origin of radial artery in 16 of 750 arms i.e.2.13% of cases. Yang et al studied 304 Korean cadavers and found high origin of radial artery in 2.3% of cases. Waghmare J E et al, 2009 described a case of high origin of radial artery with asymmetric vasculature of upper limbs. Agarwal et al in the year 2016 reported this incidence in 3.12% of cases. The present study depicts an incidence of high origin of radial artery in 5.55% cases which can be correlated with the study made by Rodríguez-Niedenführ M et al who reported the same in 6.25% of the cases. The present study depicts an incidence of high origin of radial artery in 5.55% cases which can be correlated with the study made by Rodríguez-Niedenführ M et al who reported the same in 6.25% of the cases. According to literature the variant artery often arises from the proximal third of the brachial artery but in our case it was arising from the middle third of the brachial artery 13.5 and 19 cm above the intercondylar line.

Embryological basis of the present cases can be explained if we look at the developmental stages of the upper limb arteries. The axis artery of the upper limb is derived from the lateral branch of seventh intersegmental artery (subclavian). It gives the superficial brachial artery a consistent embryonic vessel situated anterior to the cords of brachial plexus. The superficial brachial artery has two terminal branches above the elbow joint; lateral of which continued in the forearm as a part of the definitive radial artery and medial one termed as superficial antebrachial artery.

Rodríguez- Baeza et al emphasized on the fact that normal vascular development including the patterning of blood vessels is influenced greatly by local hemodynamic factors. Altered hemodynamic environment may give rise to variant patterning of blood vessels.

THE EMBRYOLOGICAL EXPLANATION OF THE PRESENT FINDINGS

The superficial antebrachial artery formed and crossed anterior to the brachial plexus (median nerve). Lateral communicating branch of the primitive axial artery or the anastomotic channel between it and superficial brachial artery did not form. There after the latter had attained the hemodynamic predominance and persisted as the radial artery as a branch of brachial artery high unpin the upper limb. It ran anterior to median nerve. The rest of the development of upper limb vasculature was normal.

CONCLUSION

All these anatomic variations theorize that each individual is and must be considered as a particular entity. Any arterial variation can have both morphological and clinical significance. Cardiologists, radiologists or vascular surgeons involved in the diagnostic and operative procedures should be vigilant of these possibilities of anatomical alterations and in case of any doubt a color Doppler ultrasound of the limb has to be carried out.
